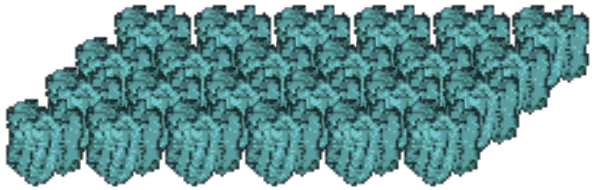
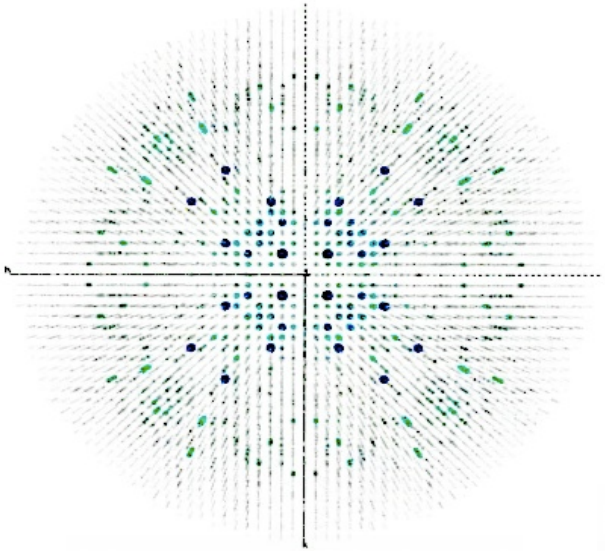
TEM in structural and cellular biology



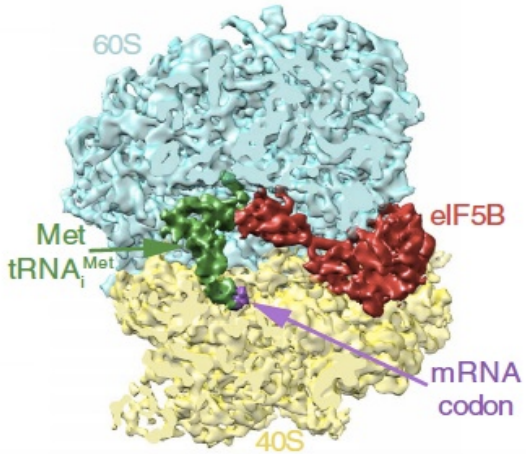
2D crystals

Electron crystallography
(views at different tilts)

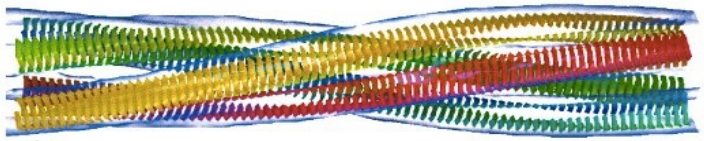


Microcrystal (<1 μm)
electron diffraction

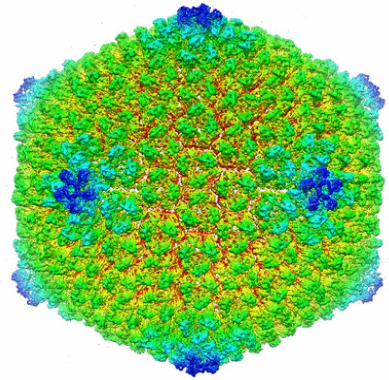
Whole cells or organelles
(**tomography** of unique objects,
cumulative irradiation)



Asymmetric **single particles**



Helical assemblies

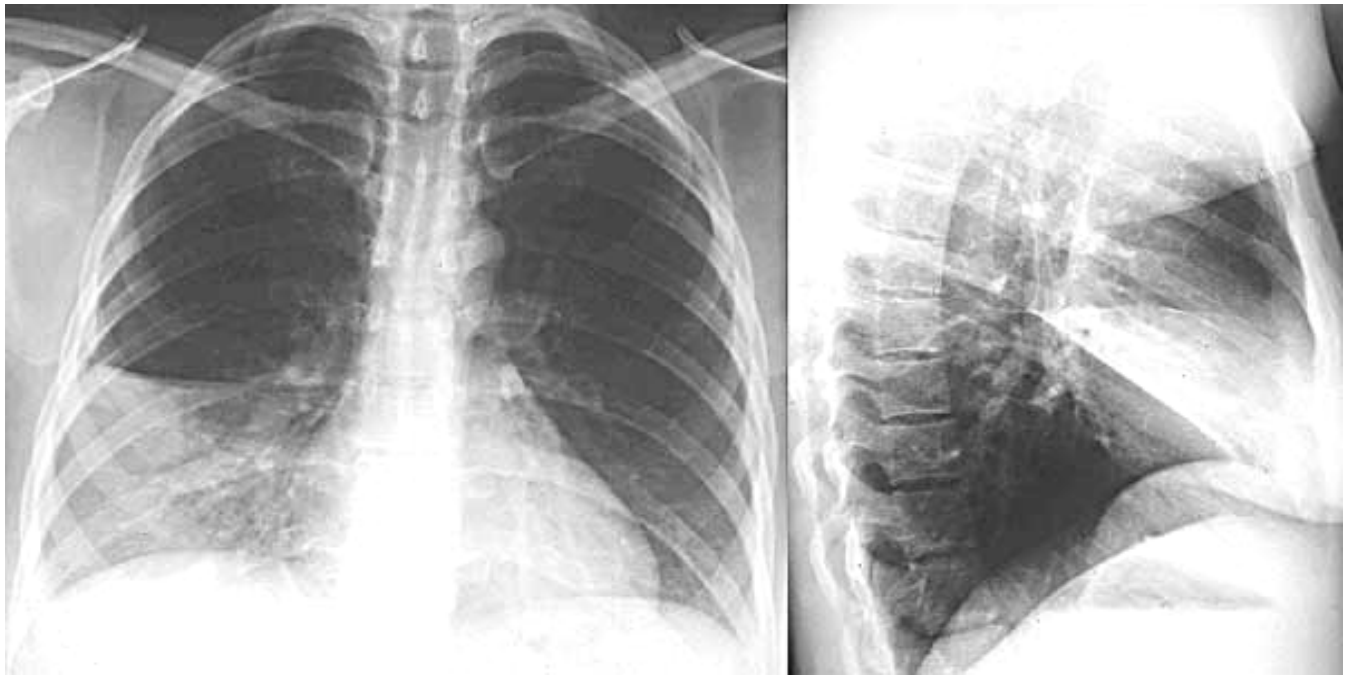


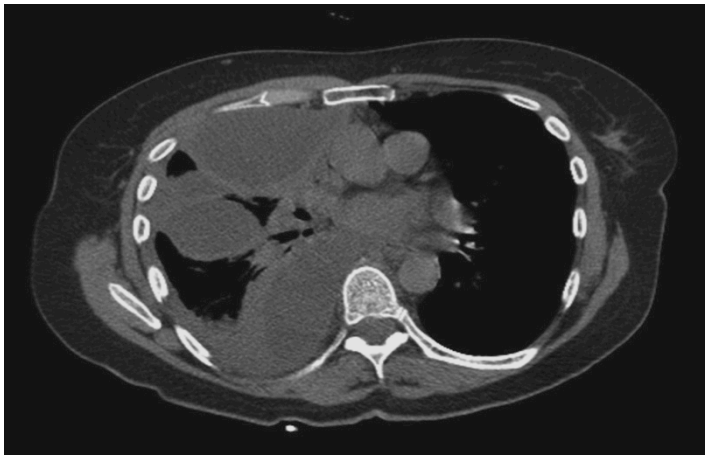
Icosahedral viruses

How is the EM image formed?

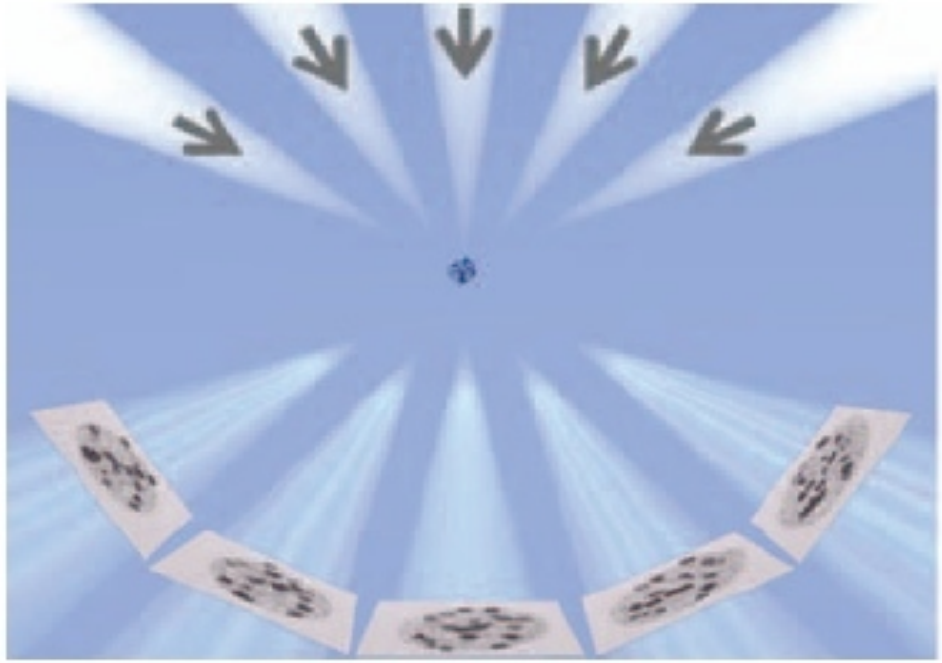
- Thin specimen scatters electrons
- Interference between scattered and unscattered electrons gives phase contrast image
- Image is 2D projection of original 3D object
- 3D structure can be determined from a set of views at different orientations
- Beam damage is the ultimate limit on resolution

Projections and sections

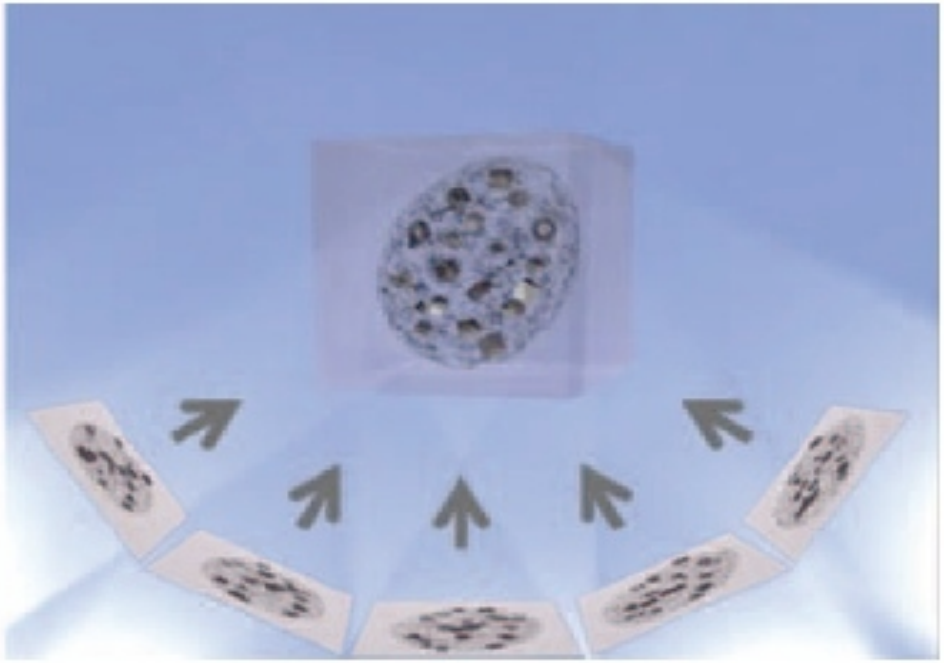




Tomographic reconstruction



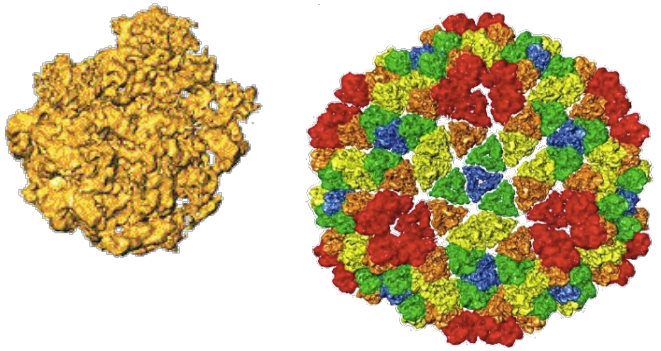
3D-object => set of 2D-projections



2D-projections => 3D-reconstruction

W Baumeister, MPI Martinsried

Single particle EM



- Isolated macromolecular complexes
- Randomly oriented in solution
- Can be trapped in different reaction states by vitrification
- No crystallization or ordered assembly needed
- The position and orientation of each particle must be determined for 3D reconstruction
- The more particles used, the higher the resolution (<2 Å)
- Mixed states can sometimes be separated (“purification in the computer”)
- Ultimate limit to resolution is radiation damage
- Interpretation by atomic structure docking or direct determination of backbone

Negative stain vs cryo EM

Negative staining

- Simple procedure
- Quick to check samples
- High contrast
- Dehydration
- Heavy metal salts
- Possible distortion, flattening

Cryo EM

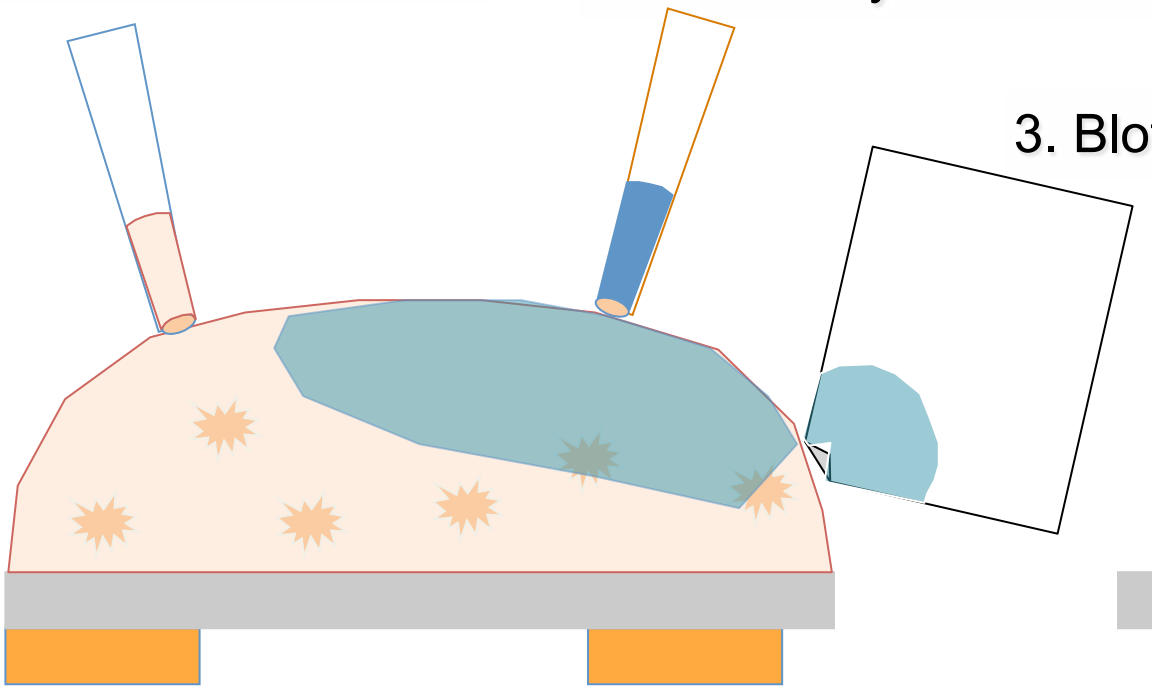
- More complex preparation
- Longer time for checking samples
- Low contrast
- Native, hydrated state
- Near physiological conditions
- 3D structure preserved
- Rapid freezing can trap transient states

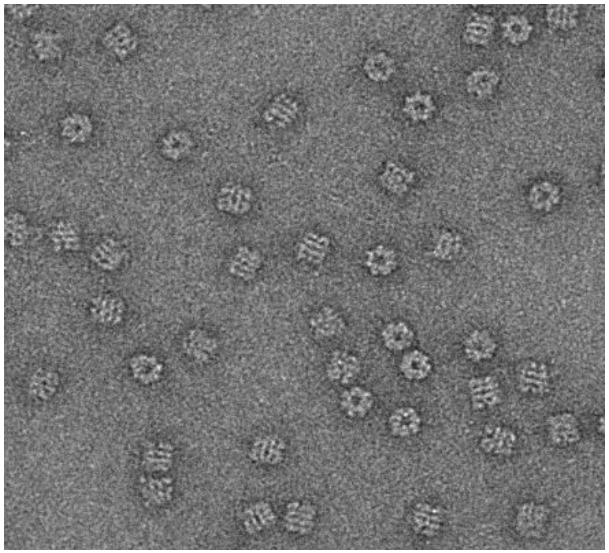
Sample preparation: Negative stain EM

1. Add protein in buffer

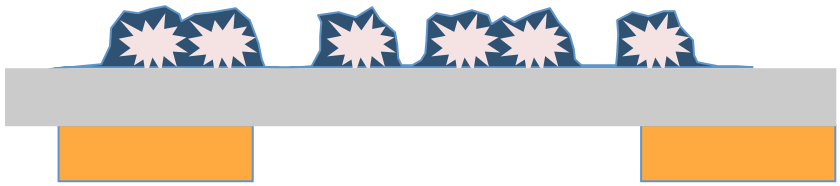
2. Add heavy metal stain

3. Blot





4. Air dry



Sample preparation: Cryo EM

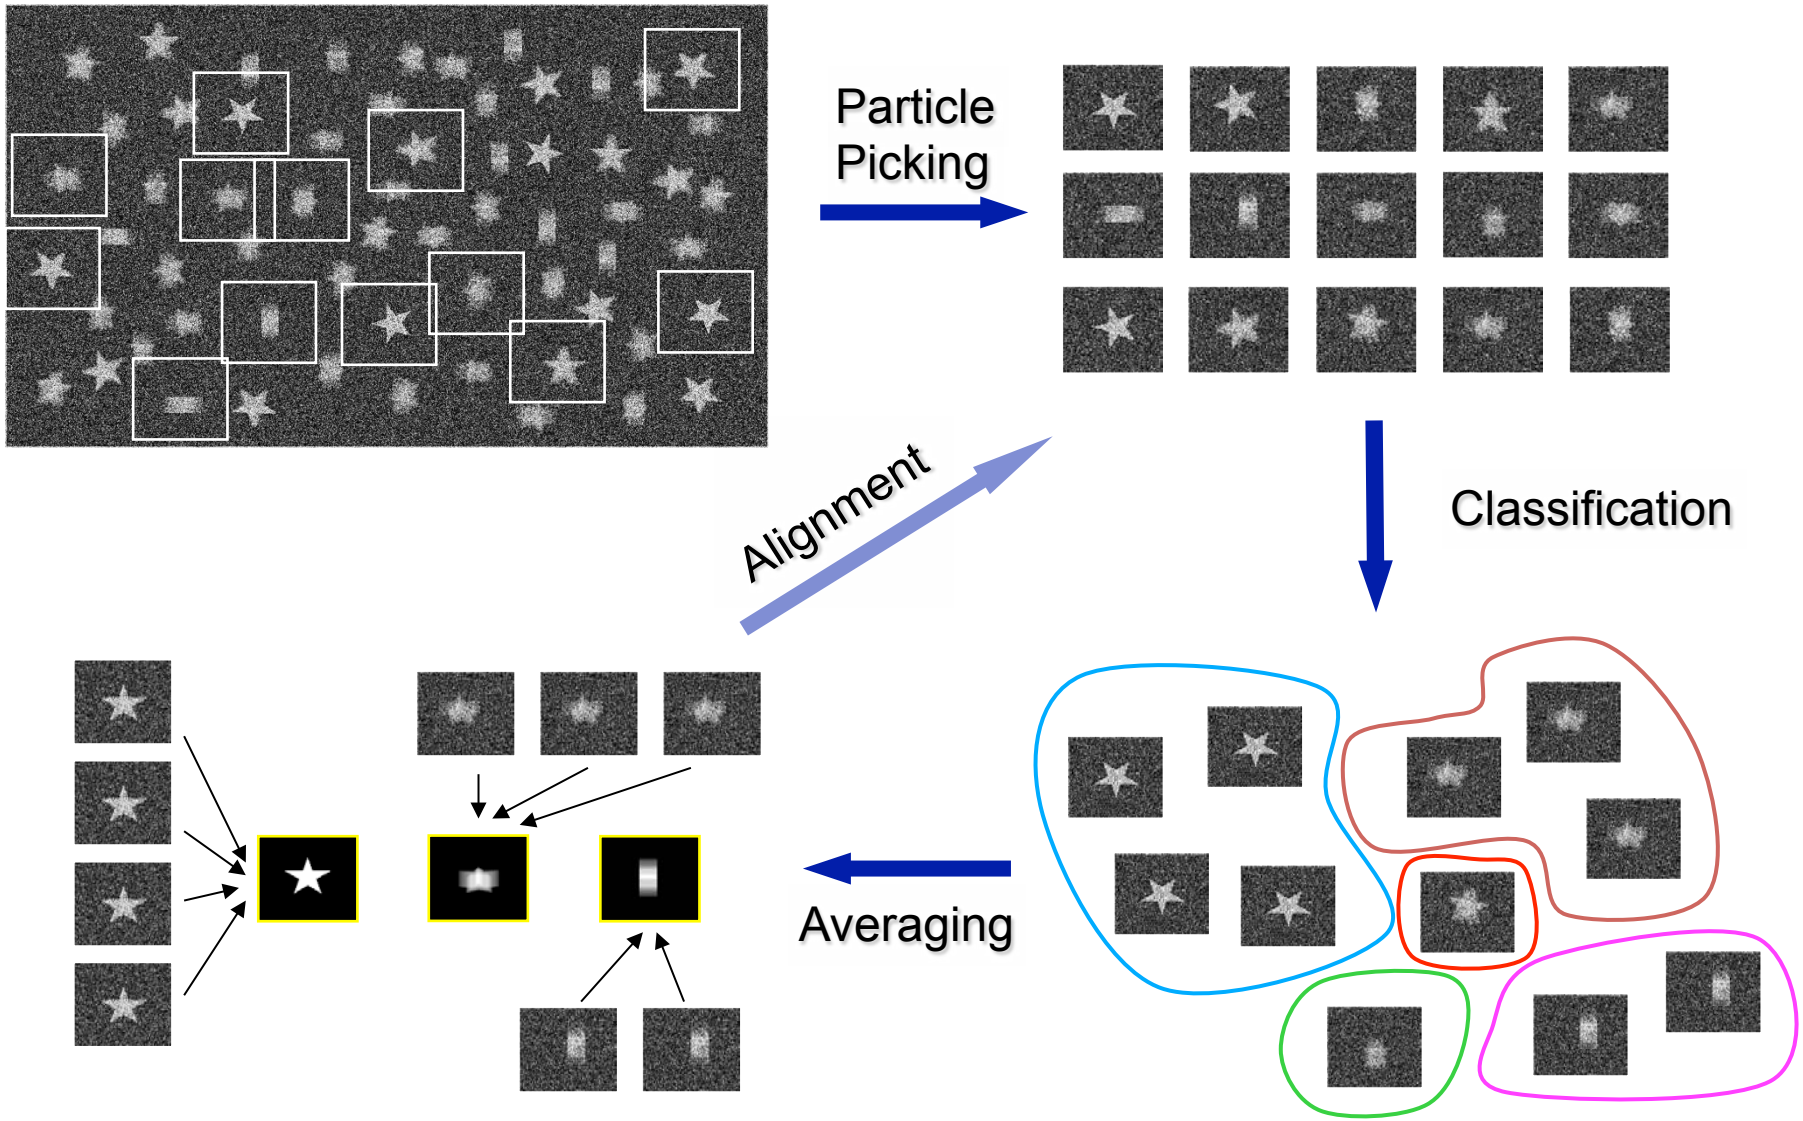
Single Particle Image Processing



Getting a starting model for a new structure

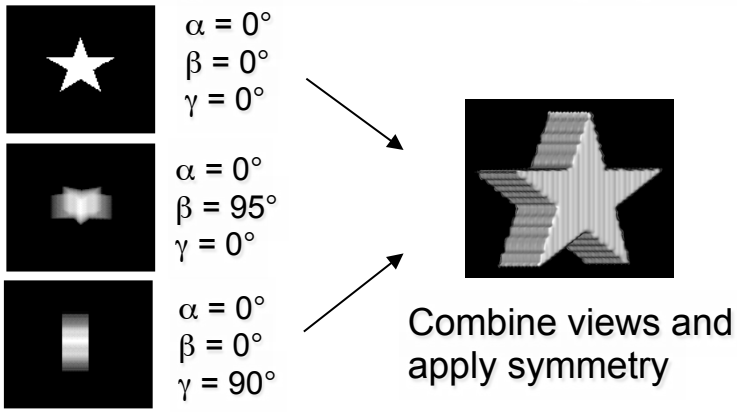
Experimental approaches

In **random conical tilt**, pairs of images are recorded of the same field of particles at high tilt and untilted, and the known angles are used to generate a 3D reconstruction (Frank, 1998).

More recently, **tomography** and **sub-tomogram averaging** have been used to determine an initial structure.

Computational approaches

In **angular reconstitution**, angles are found by searching for common line projections.



Sometimes, **projection matching to multiple initial models**, created by aligning class averages to random noise. Many models are created but only a small number lead to successful refinement.

Technological advances improve both high resolution and cellular information

- Coherent FEG sources and stable cryo stages have provided big advances in resolution and throughput
- Larger data sets and improved data processing lead to improved structures, including sorting of heterogeneous structures; merging of single particle and tomographic approaches
- Direct electron detectors offer major gains in resolution and sensitivity – movie mode enables drift correction, restoring high resolution signal; electron counting enhances DQE at all spatial frequencies
- Phase plates substantially improve contrast and extend the limits of cryo tomography and for small particles

Direct electron detectors

Power spectra

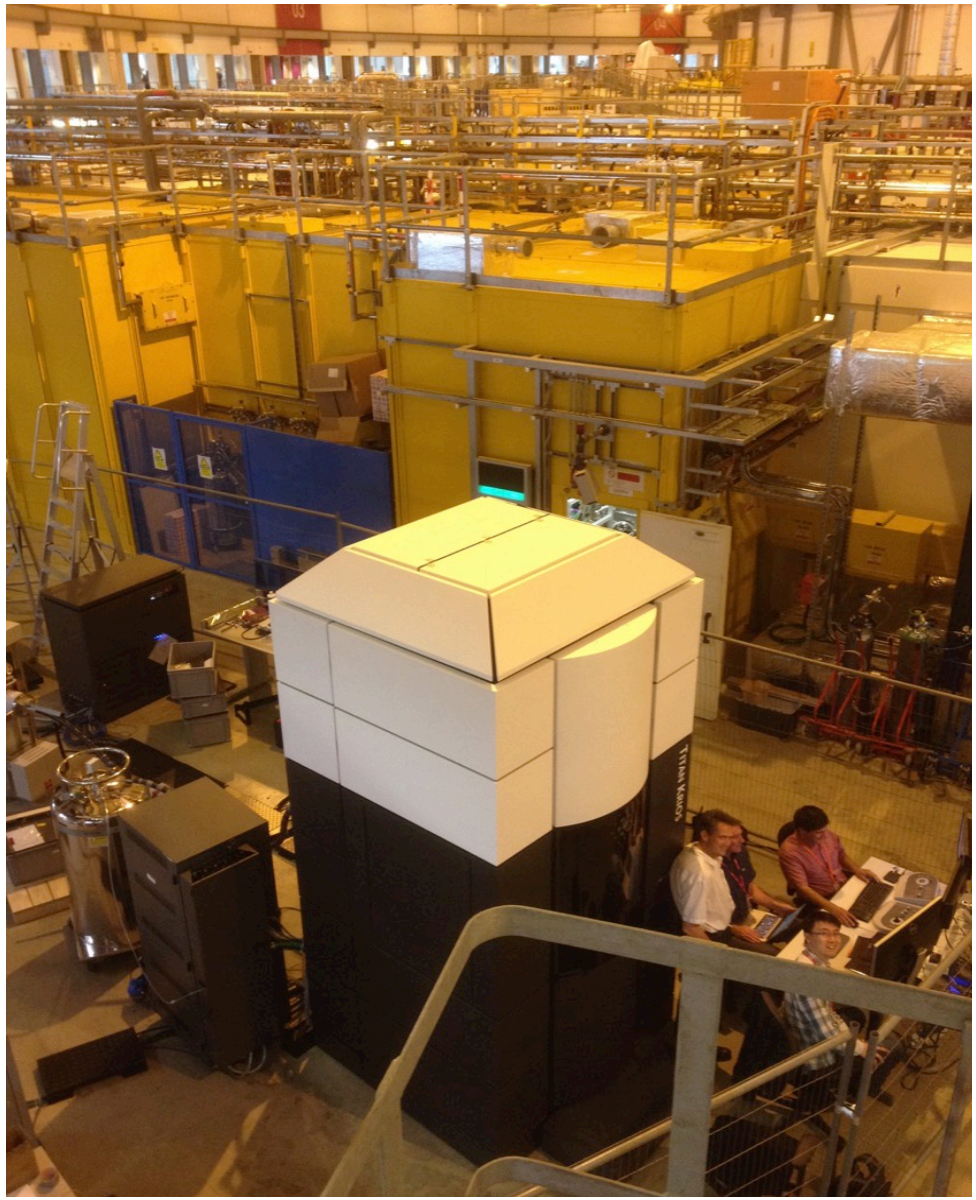
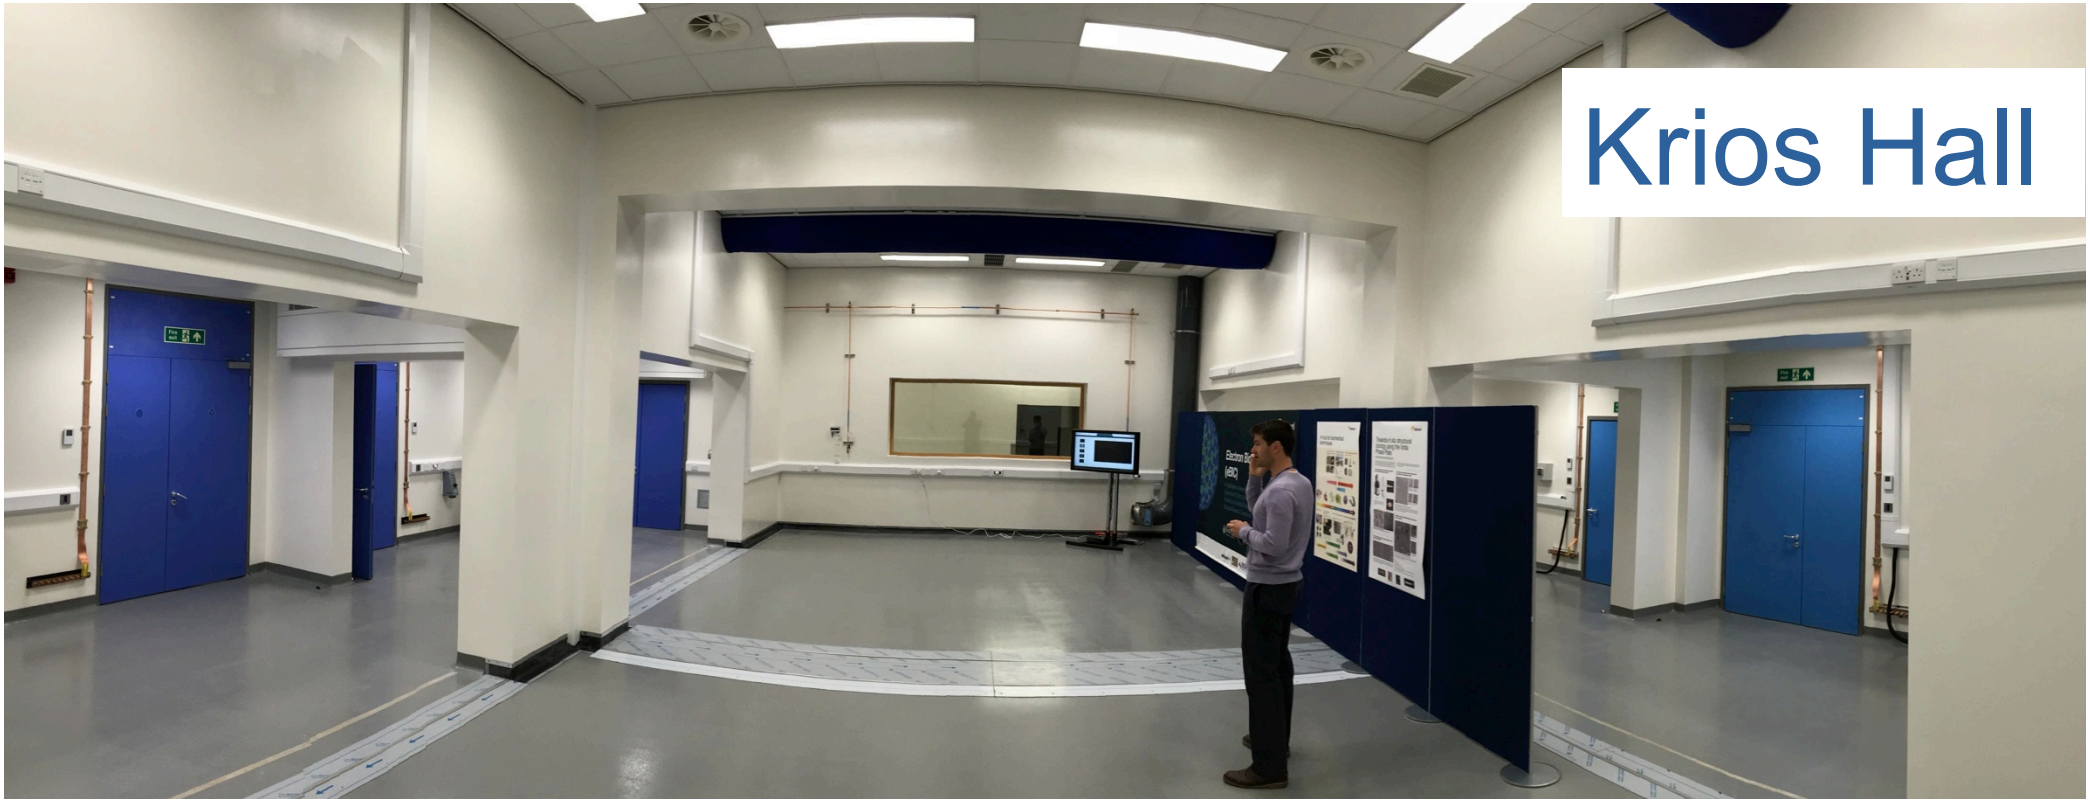
A National User Facility for Biological Electron Cryo-microscopy

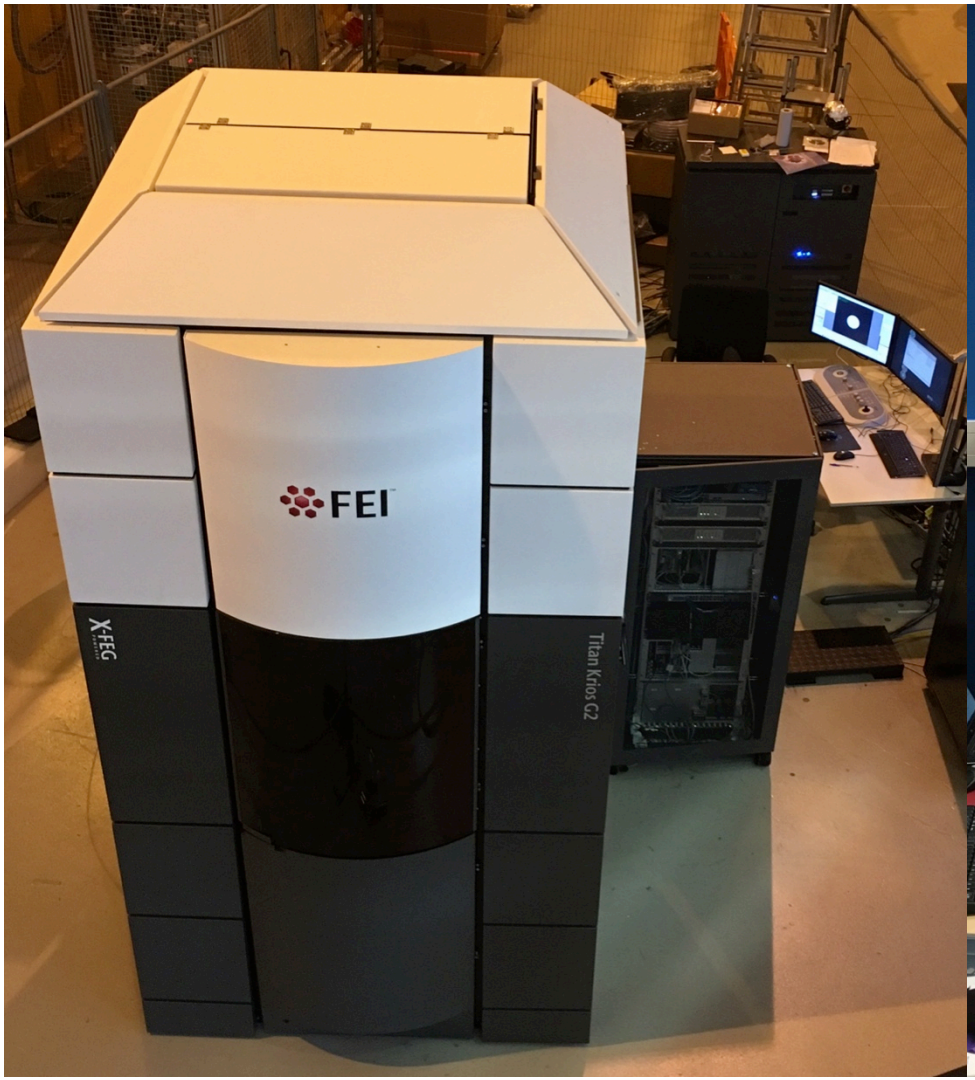
- State-of-the art facilities for single particle analysis and cryo-tomography
- Funded access, based on scientific excellence, to very expensive facilities, including biological containment facilities in Oxford (OPIC)
- Beamline-like 24/7 access supported by expert staff
- Focus for future hardware and software developments and advanced training



eBIC New Building



Krios II



The first external user session on Krios II took place on 27/06/16 and now has a full user program running

Talos

The Talos installation is almost complete and will be available for in-house testing soon

Example:

Molecular chaperones: Machines for folding and unfolding
